krandick, jebelean@risc.uni-linz.ac.at

(Received 4 July 1995)

Division of integers is called *exact* if the remainder is zero. We show that the high-order part and the low-order part of the exact quotient can be computed independently from each other. A sequential implementation of this algorithm is up to twice as fast as ordinary exact division and four times as fast as the general classical division algorithm if the dividend is twice as long as the divisor. A shared-memory parallel implementation on two processors gains another factor of two in speed.

Keywords: exact arithmetic, parallel arithmetic.

1. Introduction

Division of integers is called *exact* if the remainder is zero. Exact division arises systematically in exact calculations, e.g. when rational numbers are added or when the primitive part of an integral polynomial is computed.

Traditionally, these divisions are performed using a general quotient-remainder algorithm (e.g. "Algorithm D" of Knuth, 1981, Section 4.3.1), and then discarding the remainder. The number of digit multiplications required by this algorithm is

$$T_D(m,n) = n(m-n+1),$$

where m, n are the numbers of digits in dividend and divisor, respectively. The amount of work is suggested by the shaded area in Figure 1 – left-hand side.

Jebelean (1993a) proposed an algorithm for exact division which determines the quotient digits from right to left and requires only

$$T_J(m,n) = \begin{cases} \frac{m-n+4}{2}(m-n+1)-1 & \text{if } m \le 2n-1 \\ n(m-\frac{3}{2}n+\frac{1}{2})+m & \text{otherwise} \end{cases}$$

digit multiplications (see Corollary 3.1).

In 1994, Krandick devised an algorithm for the seemingly unrelated problem of multiple

0747–7171/90/000000 + 00 $03.00/0

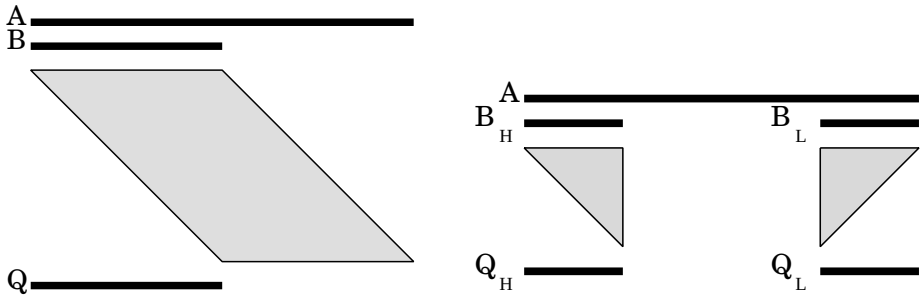

Figure 1. Classical division with remainder vs. bidirectional exact division.

precision floating point division. His method requires typically

$$T_K(m,n) = \begin{cases} n(m-n+1) & \text{if } n \le 3 \\ \frac{m-n+6}{2}(m-n+1) & \text{if } n > 3 \text{ and } m \le 2n-4 \\ n(m-\frac{3}{2}n+\frac{7}{2})-3 & \text{otherwise} \end{cases}$$

digit multiplications (see Corollary 2.1). The method is modeled after Knuth's algorithm, but it does not compute the full remainder. Instances where this would lead to an incorrect result are detected by testing a condition sufficient for correctness. The condition is efficiently computable, and it is satisfied with very high probability — if dividend and divisor are chosen at random. If, however, the remainder is zero, the condition will not be satisfied. Thus, Krandick's method cannot be used to compute all the digits of the exact quotient.

We will present an algorithm which uses Krandick's method to compute the high-order part of the exact quotient, and Jebelean's method to compute the low-order part. The combined method requires

$$T_{KJ}(m,n) \le \begin{cases} m & \text{if } n = 1 \\ \frac{(m-n)(m-n+11)}{4} + \frac{19}{8} & \text{if } n > 3 \text{ and } m \le 3n-6 \\ n(m-2n+5)-5 & \text{otherwise} \end{cases}$$

digit multiplications (see Theorem 4.1). In particular, if the dividend is twice as long as the divisor our method is almost four times as fast as the traditional method ($T_{KJ}(m,n) \le n(n+11)/4 + 19/8$, see also Figure 1 – right-hand side). The high-order part Q_H of the quotient is computed using the high-order part B_H of the divisor, while the low-order part Q_L of the quotient is computed using the low-order part B_L of the divisor. The method is well suited for coarse-grain parallelization, because the two computations are completely independent. When run in parallel on two processors, each processor has to compute at most

$$T^*_{KJ}(m,n) \le \begin{cases} \frac{2m+1}{3} & \text{if } n = 1 \\ \frac{n^2(m-n+1)+mn}{2n+1} & \text{if } n = 2,3 \\ \frac{(m-n+11)(m-n+1)}{8} & \text{if } n > 3 \text{ and } m \le 3n-6 \\ \frac{n(m-2n+6)}{2} - 3 & \text{if } n > 3 \text{ and } 3n-6 < m \le 4n-6 \\ \frac{n(m-2n+2)}{2} + \frac{m}{2} & \text{if } n > 3 \text{ and } 4n-6 < m \end{cases}$$

digit multiplications (see Theorem 5.1). In particular, if the dividend is twice as long as the divisor, the parallel version of our method is almost eight times as fast as the traditional method ($T^*_{KJ}(m,n) \le (n+1)(n+11)/8$).

This paper was first presented at a conference in 1994 (Krandick and Jebelean 1994). The idea of combining a high-order algorithm with Jebelean's exact division was first suggested to us by Schönhage, who investigated an implementation and applications together with Vetter (Schönhage and Vetter 1994). In contrast to his approach we use a different method for computing the high-order part of the quotient, we analyze the method in terms of the required number of digit products, we provide detailed empirical data, and we discuss and implement a parallel version of the method.

Coarse level parallelization of long integer division is apparently not treated in the literature. Parallel algorithms for division refer mostly to fixed-point fractions, and are designed at the level of bit processing. One research direction in this area is the theoretical investigation of time and area complexity of division on parallel computing models such as parallel random access memory (PRAM); for a survey see (Lakshmivarahan and Dhall 1990), Section 3.7. Research with practical applications is mainly VLSI-oriented (see e.g. Swartzlander, 1990), again at bit-level. Word-level algorithms are based on the systolic approach (see e.g. Jebelean, 1993b), which is too fine-grained for shared-memory architectures. Our algorithm, although not scalable, is suitable for coarse-grain parallelization on shared-memory machines and it will increase the performance of parallel algebraic algorithms which contain exact division as a subalgorithm.

Under a title quite similar to the title of this paper Văcariu (1992) treats the computation of the quotient of fixed-point numbers at bit-level. He uses the term "exact quotient" to refer to the representation of the quotient as a periodic fraction. The computation is performed from both directions, on two parallel processors, but it is organized according to a "master-slave" scheme, with communication at each step. In our algorithm only final synchronization is needed.

Section 2 describes Krandick's algorithm, Section 3 reviews Jebelean's method. Section 4 combines the two methods to maximize the performance of a sequential implementation. Section 5 shows how a parallel implementation best combines the two methods. Section 6 compares the new method empirically with the algorithms by Knuth and Jebelean and estimates at 15,000 words the break-even point against asymptotically fast division based on Karatsuba's multiplication algorithm.

2. Computing the high-order part

Given positive integers

$$A = \sum_{i=0}^{m-1} a_i \beta^i, \qquad B = \sum_{j=0}^{n-1} b_j \beta^j, \tag{2.1}$$

of *β-length* $m, n \ge 1$ and with *β-digits* $0 \le a_i, b_j < \beta$ and $a_{m-1}, b_{n-1} > 0$, we want to find the h high-order digits of $Q = \lfloor A/B \rfloor$, where $1 \le h \le m-n+1$. Here we consider Q as having $m-n+1$ digits, with the high-order digit being possibly zero. In other words, we want to compute

$$\bar{Q} = \left\lfloor A/\bar{B} \right\rfloor,$$

where $\bar{B} = B\beta^{m-n+1-h}$.

Traditional classical division requires hn digit multiplications for this task. We will

describe a method that typically requires only $h(h+5)/2$ digit multiplications when $n > 3$ and $h \leq n-3$. The savings are obtained by suppressing the computation of the remainder.

Instead of computing $\bar{Q}$ and $\bar{R}$, $0 \leq \bar{R} < \bar{B}$, with

$$A = \bar{Q} \cdot \bar{B} + \bar{R}$$

we compute Q^* and R^* such that

$$A = Q^* \circ \bar{B} + R^*,$$

where $Q^* \circ \bar{B}$ is a well-defined approximation to the product $Q^*\bar{B}$. Computing $Q^* \circ \bar{B}$ requires fewer digit products than computing the exact product $Q^*\bar{B}$.

We will define the approximate product $\circ$ and derive an error bound

$$\epsilon \geq Q^*\bar{B} - Q^* \circ \bar{B}.$$

We will state a condition involving ϵ and R^* which will be easy to test and which will imply equality of Q^* and $\bar{Q}$. We will argue that Q^* can be determined in such a way that the sufficient condition will be satisfied with high probability.

Definition 2.1. *Let A, B be integers as in (2.1) with B having n digits. We define the* approximate product

$$A \circ B = \sum_{i+j \geq n-3} a_i b_j \beta^{i+j}.$$

Clearly, for $n = 1, 2$ or 3, the approximate product coincides with the exact product. In the notation of Krandick and Johnson (1993a), $A \circ B = (A \times_{n-1} B)\beta^{n-3}$ where $\times_{n-1}$ denotes "the short product with respect to $(n-1)$". The deviation from the exact product can be estimated as follows.

Proposition 2.1. *Let A,B as in (2.1) with B having n digits, let*

$$\delta = \begin{cases} 0 & \text{if } n = 1, 2 \\ (n-3)\beta^{n-2} & \text{if } n \geq 3. \end{cases}$$

Then

$$A \circ B \leq AB \leq A \circ B + \delta.$$

Proof. The cases $n = 1, 2$ are trivial. By induction on $n \geq 3$,

$$\sum_{i+j<n-3} (\beta-1)^2 \beta^{i+j} \leq (n-3)\beta^{n-2} + (2-n)\beta^{n-3} + 1.$$

The right-hand side is $\leq \delta$. This proves the second inequality. □

The proposed division method uses the approximate product of Q^* and $\bar{B}$. Noting that $\bar{B}$ has $m-h+1$ digits we obtain

$$Q^* \circ \bar{B} = \sum_{i+j \geq m-h-2} q_i^* \bar{b}_j \beta^{i+j}, \tag{2.2}$$

with $Q^* = \sum_{i=0}^{h-1} q_i^* \beta^i$, $0 \leq q_i^* < \beta$ and with $\bar{B} = \sum_{j=0}^{m-h} \bar{b}_j \beta^j$, $0 \leq \bar{b}_j < \beta$. Furthermore,

we have

$$Q^* \circ \bar{B} \le Q^* \bar{B} \le Q^* \circ \bar{B} + \epsilon, \tag{2.3}$$

where

$$\epsilon = \begin{cases} 0 & \text{if } m-h = 0,1 \\ (m-h-2)\beta^{m-h-1} & \text{if } m-h \ge 2. \end{cases} \tag{2.4}$$

We now give a sufficient condition for the success of the method.

PROPOSITION 2.2. *Let ϵ as in (2.4). If*

$$\epsilon \le R^* < \bar{B} \tag{2.5}$$

then

$$Q^* = \bar{Q}.$$

PROOF. Let

$$R^{**} = A - Q^* \bar{B}$$

and assume (2.5). Then (2.3) implies

$$R^{**} = (Q^* \circ \bar{B} + R^*) - Q^* \bar{B} \ge (Q^* \circ \bar{B} + \epsilon) - Q^* \bar{B} \ge 0$$

and

$$R^{**} \le A - Q^* \circ \bar{B} = R^* < \bar{B}.$$

Hence, $A = Q^* \bar{B} + R^{**}$ with $0 \le R^{**} < \bar{B}$, so Q^* must be the desired quotient $\bar{Q}$. □

The proposed division method will produce a Q^* such that $A = Q^* \circ \bar{B} + R^*$. It will be shown that $Q^* = \bar{Q}$ with high probability. Condition (2.5) will be used to establish $Q^* = \bar{Q}$ with certainty. Therefore, the following question has to be discussed. Given $Q^* = \bar{Q}$, what is the probability that condition (2.5) is satisfied? — Because of (2.3) we have

$$A - Q^* \circ \bar{B} \ge A - Q^* \bar{B} \ge A - Q^* \circ \bar{B} - \epsilon.$$

Hence, letting $Q^* = \bar{Q}$ in the middle,

$$R^* \ge \bar{R} \ge R^* - \epsilon$$

or, equivalently,

$$\bar{R} \le R^* \le \bar{R} + \epsilon.$$

Thus, condition (2.5) will be satisfied if

$$\epsilon \le \bar{R} < \bar{B} - \epsilon. \tag{2.6}$$

If all possible values $0, \ldots, \bar{B}-1$ for $\bar{R}$ are equally likely, (2.6) is true with probability

$$\frac{\bar{B} - 2\epsilon}{\bar{B}} \ge 1 - \frac{2(m-h-2)\beta^{m-h-1}}{\bar{B}} \ge 1 - \frac{2(m-h-2)}{\beta}.$$

This value is very close to 1 if β is the word size of a computer (e.g. $\beta = 2^{32}$).

The digits of Q^* are determined by Algorithm H in Figure 3 analogously to "Algorithm D" of Knuth (1981, p.257). We assume radix β to be a power of 2, for example the word

Algorithm H (*High-order part of quotient*). Let A, B as in (2.1) with m and n digits, respectively, and let $1 \leq h \leq m - n + 1$. The algorithm will compute the h high-order digits $q_{m-n}, \ldots, q_{m-n-h+1}$ of $\lfloor A/B \rfloor$ or fail. The probability of a failure is very small. We may assume $m \geq n > 1$, and $m = n$ only if $a_{m-1} \geq b_{n-1}$.

H1. [Normalize.] Set $d \leftarrow$ the number of leading 0-bits in b_{n-1}, $I \leftarrow \max(0, m - n - h)$. Then perform the left-shifts $[a_m, a_{m-1}, \ldots, a_I] \leftarrow [a_{m-1}, \ldots, a_I] * 2^d$ and $[b_{n-1}, \ldots, b_0] \leftarrow [b_{n-1}, \ldots, b_0] * 2^d$.
H2. [Initialize loop.] Set $k \leftarrow m - n$, $i \leftarrow m$.
H3. [Calculate quotient digit.] If $a_i \geq b_{n-1}$, set $q_k \leftarrow \beta - 1$; otherwise set $q_k \leftarrow \lfloor [a_i, a_{i-1}]/b_{n-1} \rfloor$. Subtract $b_{n-1} q_k$ from $[a_i, a_{i-1}]$; then subtract $b_{n-2} q_k$ from $[a_i, a_{i-1}, a_{i-2}]$. If this leaves a_i negative, decrement q_k by 1 and add $[b_{n-1}, b_{n-2}]$ to $[a_i, a_{i-1}, a_{i-2}]$.
H4. [Multiply and subtract.] Set $J \leftarrow \max(0, m - h - 2 - k)$; then subtract $[b_{n-3}, \ldots, b_J] * q_k$ from $[a_i, \ldots, a_{k+J}]$.
H5. [Test remainder.] If $a_i \geq 0$, go to step H7.
H6. [Add back.] Decrement q_k by 1; add $[b_{n-1}, \ldots, b_J]$ to $[a_i, \ldots, a_{k+J}]$.
H7. [Remainder overflow?] If $a_i \neq 0$ then fail.
H8. [Loop on k.] If $k > m - n - h + 1$, decrement k and i by 1 and go back to H3.
H9. [Final remainder too small?] If $a_{m-h} = 0$ and $a_{m-h-1} < m - h - 2$ then fail.
H10. [Final remainder too large?] If $[a_{m-h}, \ldots, a_{m-n+1-h}] \geq [b_{n-1}, \ldots, b_0]$ then fail.

Figure 2. Computing the high-order part of the quotient.

size of the computer. We represent β-digits as words; hence we may refer in step H1 to the number of leading 0-bits of a β-digit. The normalization is effected by a binary shift which is applied to all digits of B, but only to those digits of A that will be needed in step H10. Steps H3 and H4 together subtract $[b_{n-1}, \ldots, b_J] * q_k$ from $[a_i, \ldots, a_{k+J}]$ with $J = \max(0, m - h - 2 - k)$. In total, the loop subtracts $[q_{m-n}, \ldots, q_{m-n-h+1}] \circ [b_{n-1}, \ldots, b_0, 0, \ldots, 0] = [q^*_{m-n}, \ldots, q^*_{m-n-h+1}] \circ [\bar{b}_{m-h}, \ldots, \bar{b}_{m-n-h+1}, \bar{b}_{m-n-h}, \ldots, \bar{b}_0] = Q^* \circ \bar{B}$ from $[a_m, \ldots, a_0]$. This motivates the analysis in Proposition 2.3. Steps H9 and H10 test for the condition of Proposition 2.2.

We will now argue that the loop in Algorithm H will produce $\bar{Q}$ with high probability. Knuth (1981) shows in exercise 4.3.1.21 that step D3 of his algorithm will fail to supply the correct quotient digit with approximate probability $2/\beta$. This number is very small when β is the word size of a computer. For Algorithm H this means that quotient digit q_{i-n} calculated in step H3 will be correct in almost all cases where the three leading digits a_i, a_{i-1}, a_{i-2} of the current "remainder" are correct. We will argue inductively that for $i = m, \ldots, m - h + 2$ the values of a_i, a_{i-1}, a_{i-2} are most likely correct.

At the beginning of the algorithm the values of a_m, a_{m-1}, a_{m-2} are clearly correct. For the induction step we assume that a_i, a_{i-1}, a_{i-2} are correct at the beginning of step H3. Under this assumption the value of q_{i-n} at the end of step H3 is correct with approximate probability $2/\beta$. In step D4 of Knuth's algorithm q_{i-n} is multiplied by all digits of the divisor; in step H4 of Algorithm H some of these multiplications are skipped. The probability that this deliberate error affects the values of a_i, a_{i-1}, a_{i-2} in step H7 is bounded above by the probability that adding ϵ to $Q^* \circ \bar{B}$ produces a carry into the $h+1$ high-order digits (according to (2.3), $Q^* \circ \bar{B} \leq Q^* \bar{B} \leq Q^* \circ \bar{B} + \epsilon$). A carry can only be produced if $a_{m-h-1} \geq \beta - (m-h-2)$. But this is highly unlikely; experiments by Krandick and Johnson (1993b) seem to indicate that all numbers $0, \ldots, \beta - 1$ are equally likely as values of a_{m-h-1}. Under this assumption, the probability that $a_{m-h-1} \geq \beta - (m-h-2)$ is $(m - h - 2)/\beta$. This is very small, so the values of a_i, a_{i-1}, a_{i-2} in step H7 are most likely correct.

We note that step H7 is not necessary in Knuth's algorithm. In our algorithm, however, the value of a_i might be positive (and not zero as it should be), because we are not

subtracting enough in step H4. For the same reason, the value of a_i in step H3 might be too large. By letting $q_k \leftarrow \beta - 1$ if $a_i \geq b_{n-1}$ we make sure that in any event q_k will be less than β.

The inductive argument shows that $q_{m-n}, \ldots, q_{m-n-h+2}$ are most likely to be correct. If this is the case, $[a_{m-h+1}, a_{m-h}, a_{m-h-1}]$ deviates from its true value by at most $m - h - 2$, so also the last quotient digit $q_{m-n-h+1}$ will most likely be correct.

Thus, the number Q^* produced by the loop in Algorithm H is equal to $\bar{Q}$ with a probability in the neighborhood of $1 - 1/\beta$. We have argued above that in case $Q^* = \bar{Q}$ the tests in steps H9 and H10 will be passed with probability $\geq 1 - 2(m - h - 2)/\beta$. So, Algorithm H will succeed with a probability close to 1. When we used the algorithm in a million randomly generated test cases to compute the high 25 words of the exact quotient of a 100-word number and a 50-word number, there was not a single case of failure. The word size in this experiment was $\beta = 2^{29}$. If Algorithm H fails, the method of Section 3, which is fail-safe, can be used to compute all the digits of the exact quotient.

PROPOSITION 2.3. *The number $\mu(n, h)$ of digit products in formula (2.2) is*

$$\mu(n,h) = \begin{cases} nh & \text{if } n \leq 3 \\ \frac{h(h+5)}{2} & \text{if } n > 3 \text{ and } h \leq n-3 \\ \frac{2hn - n^2 + 5n - 6}{2} & \text{if } n > 3 \text{ and } h > n-3. \end{cases} \tag{2.7}$$

PROOF. For each index $i = 0, \ldots, h-1$ index j ranges from $\max(0, m-h-2-i)$ to $m-h$, but since $\bar{b}_0 = \ldots = \bar{b}_{m-h-n} = 0$, only the $j \geq m-h-n+1$ have to be considered. Hence the number μ_i of digit products for a given i is

$$\begin{aligned} \mu_i &= (m-h) + 1 - \max((m-h) - (n-1), 0, (m-h) - (2+i)) \\ &= (m-h) + 1 - \max(0, (m-h) - \min(n-1, 2+i)). \end{aligned}$$

The expression can be simplified by distinguishing two cases.

1 In case $i \geq n-3$ we have $n-1 \leq 2+i$, so

$$\mu_i = (m-h) - \max(0, (m-h) - (n-1)) + 1.$$

Noting that $(m-h) - (n-1) \geq 0$ since $h \leq m-n+1$, we obtain

$$\mu_i = (m-h) - ((m-h) - (n-1)) + 1 = n.$$

2 In case $i < n-3$ we have $n-1 > 2+i$, so

$$\mu_i = (m-h) - \max(0, (m-h) - (2+i)) + 1.$$

Since $i < n-3 \leq m-h-2$, the expression evaluates to

$$\mu_i = (m-h) - ((m-h) - (2+i)) + 1 = 3 + i.$$

Knowing the μ_i we can now verify the three cases of the proposition.

1 In case $n \leq 3$ we have $n-3 \leq 0 \leq h-1$, so all i are $\geq n-3$, hence all $\mu_i = n$ and so there are

$$\mu(n,h) = \sum_{i=0}^{h-1} \mu_i = nh$$

digit products.

2 In case $n > 3$ and $h \leq n-3$ we have $0 \leq h-1 < n-3$, so all indices i are $< n-3$, hence all $\mu_i = 3+i$ and so there are

$$\mu(n,h) = \sum_{i=0}^{h-1}(3+i) = \frac{h(h+5)}{2}$$

digit products.

3 In case $n > 3$ and $h > n-3$ we have $0 < n-3 \leq h-1$, so there are

$$\mu(n,h) = \sum_{i=0}^{n-4}(3+i) + \sum_{i=n-3}^{h-1} n = \frac{2hn - n^2 + 5n - 6}{2}$$

digit products.

□

COROLLARY 2.1. *Letting $h = m-n+1$ in Proposition 2.3 we obtain*

$$T_K(m,n) = \begin{cases} n(m-n+1) & \text{if } n \leq 3 \\ \frac{m-n+6}{2}(m-n+1) & \text{if } n > 3 \text{ and } m \leq 2n-4 \\ n(m-\frac{3}{2}n+\frac{7}{2})-3 & \text{otherwise.} \end{cases}$$

3. Computing the low-order part

Let A and B as in (2.1), and assume that B divides A. The exact division algorithm of Jebelean (1993a) exploits the implication

$$(A'\beta + a_0) = (B'\beta + b_0) * (Q'\beta + q_0) \quad \Rightarrow \quad a_0 = (b_0 q_0) \bmod \beta.$$

The latter equation can be used to compute q_0

$$q_0 = (a_0 (b_0)^{-1}_{\bmod \beta})_{\bmod \beta}$$

— provided $\mathrm{GCD}(b_0, \beta) = 1$. When β is a power of 2 this condition can be ensured by shifting A and B to the right until b_0 becomes odd. After the least-significant quotient digit q_0 has been found, A is replaced by

$$(A - q_0 B)/\beta = Q' * B,$$

and the procedure is repeated to find q_1, and so on. This method is faster than the traditional classical algorithm, because only the l low-order digits of the intermediate results $A - q_0 B$ etc. have to be computed in order to determine the l low-order digits of the quotient. Algorithm L in Figure 3 takes advantage of this insight. We may assume that the least-significant β-digit of B is non-zero; indeed, A must have at least as many trailing zero β-digits as B, and common trailing zeros can be deleted without affecting the quotient.

When analyzing Algorithm L, we will not consider the (constant) cost of finding the modular inverse of b_0 in step L2. Jebelean (1993a) shows that b_0 can be inverted using one or two digit multiplications and a table look-up when β is a power of 2; the extended Euclidean algorithm need not be applied. In our experiments the modular inverse costs as much as 2.25 digit products.

Algorithm L (*Low-order part of quotient*). Let A, B be as in (2.1) with m and n digits, respectively, with $A \bmod B = 0$ and with $b_0 \neq 0$, and let $1 \leq l \leq m - n + 1$. The algorithm will compute the l low-order digits $q_{l-1}, \ldots, q_0$ of $Q = A/B$.

L1. [Right-shift.] Set $d \leftarrow$ the number of trailing 0-bits in b_0, and set $L \leftarrow \min(n, l)$. Then perform the right-shifts $[a_{l-1}, \ldots, a_0] \leftarrow [a_l, a_{l-1}, \ldots, a_0]/2^d$ and $[b_{L-1}, \ldots, b_0] \leftarrow [b_L, b_{L-1}, \ldots, b_0]/2^d$.
L2. [Compute modular inverse.] Set $b' \leftarrow (b_0)^{-1}_{\bmod \beta}$.
L3. [Initialize loop.] Set $k \leftarrow 0$.
L4. [Calculate quotient digit.] Set $q_k \leftarrow (b' * a_k)_{\bmod \beta}$.
L5. [Test termination] If $k = l - 1$ then STOP.
L6. [Multiply and subtract.] Set $J \leftarrow \min(L, l - k)$; then subtract $[b_{J-1}, \ldots, b_0] * q_k$ from $[a_{l-1}, \ldots, a_k]$.
L7. [Loop.] Increment k and go back to step L4.

Figure 3. Computing the low-order part of the quotient.

PROPOSITION 3.1. *The number $\nu(n, l)$ of digit products in Algorithm L is*

$$\nu(n,l) = \begin{cases} \frac{l(l+3)}{2} - 1 & \text{if } l \leq n \\ l(n+1) - \frac{n^2-n+2}{2} & \text{if } l > n. \end{cases} \tag{3.1}$$

PROOF. Let $L = \min(n, l)$. We will show that

$$\nu(n,l) = l(L+1) - \frac{L^2 - L + 2}{2}. \tag{3.2}$$

From Algorithm L we obtain

$$\begin{aligned} \nu(n,l) &= l + \sum_{k=0}^{l-2} \min(L, l-k) \\ &= l + \sum_{k=0}^{\min(l-2, l-L)} L + \sum_{k=\max(0, \min(l-2, l-L)+1)}^{l-2} (l-k) \\ &= l + \sum_{k=0}^{l-\max(2,L)} L + \sum_{k=\max(0, l-\max(2,L)+1)}^{l-2} (l-k). \end{aligned}$$

1 If $L = 1$ we have

$$\nu(n,l) = l + \sum_{k=0}^{l-2} 1 + \sum_{k=l-1}^{l-2} (l-k) = l + (l-1) + 0 = 2l - 1.$$

2 If $L = 2$ we have

$$\nu(n,l) = l + \sum_{k=0}^{l-2} 2 + \sum_{k=l-1}^{l-2} (l-k) = l + 2(l-1) + 0 = 3l - 2.$$

3 If $L > 2$ we have

$$\nu(n,l) = l + \sum_{k=0}^{l-L} L + \sum_{k=l-L+1}^{l-2} (l-k) = l + (l-L+1)L + \frac{(L-2)(L+1)}{2}.$$

In all three cases equation (3.2) is satisfied; and equation (3.2) implies equation (3.1). □

COROLLARY 3.1. *Letting $l = m - n + 1$ in Proposition 3.1 we obtain*

$$T_J(m,n) = \begin{cases} \frac{m-n+4}{2}(m-n+1) - 1 & \text{if } m \le 2n-1 \\ n(m - \frac{3}{2}n + \frac{1}{2}) + m & \text{otherwise.} \end{cases}$$

This result corrects the analysis given in the original paper (Jebelean 1993a), which did not account for the digit multiplications in step L4 of the algorithm.

4. Sequential exact division

The digits of the exact quotient can be computed sequentially by first using Algorithm H to calculate the high-order part of the quotient and then Algorithm L for the low-order part. This is most efficient when the quotient is split in such a way that the combined number of digit products is minimized.

DEFINITION 4.1. *Let $\mu(n,h)$ as in (2.7), $\nu(n,l)$ as in (3.1), and let $\mu(n,0) = \nu(n,0) = 0$. Now define $T_{KJ}(m,n) = \min_{0 \le h \le m-n+1} \mu(n,h) + \nu(n, m-n+1-h)$.*

In order to avoid a profusion of unproductive case distinctions we only give an upper bound for $T_{KJ}(m,n)$.

THEOREM 4.1.

$$T_{KJ}(m,n) \le \begin{cases} m & \text{if } n = 1 \\ \frac{(m-n)(m-n+11)}{4} + \frac{19}{8} & \text{if } n > 3 \text{ and } m \le 3n-6 \\ n(m-2n+5) - 5 & \text{otherwise.} \end{cases}$$

PROOF. Let

$$h = \begin{cases} m & \text{if } n = 1 \\ \lfloor \frac{m-n}{2} \rfloor & \text{if } n > 3 \text{ and } m \le 3n-6 \\ m - 2n + 2 & \text{otherwise,} \end{cases} \tag{4.1}$$

and let $l = m - n + 1 - h$. Now the desired inequality is obtained by bounding $\mu(n,h) + \nu(n,l)$ from above. For easy application of equations (2.7) and (3.1) we distinguish the following cases.

1 In case $n = 1$ the result is straightforward.
2 In case $n > 3$ and $m \le 3n - 6$ let $\tilde{h} = (m-n)/2$ and $\tilde{l} = (m-n+3)/2$. Then $h \le \tilde{h} \le n-3$, $l \le \tilde{l} < n$ and

$$\mu(n,h) + \nu(n,l) \le \mu(n,\tilde{h}) + \nu(n,\tilde{l}) = \frac{m-n}{4}(m-n+11) + \frac{19}{8}.$$

3 In case $n > 3$ and $m = 3n-5$ we have $h = n-3$, $l = n-1$, and $\mu(n,h) + \nu(n,l) = n^2 - 5 = n(m-2n+5) - 5$.
4 In case $n > 3$ and $m > 3n-5$ we have $h > n-3$, $l = n-1$ and $\mu(n,h) + \nu(n,l) = n(m-2n+5) - 5$.
5 In case $n = 2,3$ we have $h = m-2n+2$, $l = n-1$ and $\mu(n,h) + \nu(n,l) = (2mn - 3n^2 + 5n - 4)/2$. For $n = 2,3$ this equals $n(m-2n+5) - 5$.

□

5. Parallel exact division

The high-order and the low-order part of the exact quotient can be computed by executing Algorithm H and Algorithm L in parallel on two processors. This is most efficient when the quotient is split in such a way that the number of digit products in either algorithm is minimized.

DEFINITION 5.1. *Let $\mu(n,h)$ and $\nu(n,l)$ as in Definition (4.1). Define* $T^*_{KJ}(m,n) = \min_{0\le h\le m-n+1} \max(\mu(n,h),\nu(n,m-n+1-h))$.

For simplicity we only give an upper bound for $T^*_{KJ}(m,n)$.

THEOREM 5.1.

$$T^*_{KJ}(m,n) \le \begin{cases} \frac{2m+1}{3} & \text{if } n=1 \\ \frac{n^2(m-n+1)+mn}{2n+1} & \text{if } n=2,3 \\ \frac{(m-n+11)(m-n+1)}{8} & \text{if } n>3 \text{ and } m\le 3n-6 \\ \frac{n(m-2n+6)}{2}-3 & \text{if } n>3 \text{ and } 3n-6<m\le 4n-6 \\ \frac{n(m-2n+2)}{2}+\frac{m}{2} & \text{if } n>3 \text{ and } 4n-6<m. \end{cases}$$

PROOF. Let

$$h = \begin{cases} \left\lceil \frac{n+1}{2n+1}(m-n) \right\rceil & \text{if } n\le 3 \\ \left\lceil \frac{m-n}{2} \right\rceil & \text{otherwise,} \end{cases} \tag{5.1}$$

and let $l = m-n+1-h$.

We first prove the theorem for the case $n \le 3$.

1 The first branch of ν in (3.1) is only relevant if $n=1$ and $m=1,2,3$ or if $n=2$ and $m=2,\ldots,6$ or if $n=3$ and $m=3,\ldots,9$. In each of these 15 cases the theorem can be verified explicitly.

2 If m and n are such that ν is defined by its second branch in (3.1), we handle the ceiling function in the definition of h by letting

$$\tilde{h} = \frac{(n+1)(m-n)+2n}{2n+1} \ge h.$$

Since the first branch of μ in (2.7) is monotone increasing in h we have

$$\mu(n,h) \le \mu(n,\tilde{h}) = \frac{n^2(m-n+1)+mn}{2n+1}.$$

Furthermore, let

$$\tilde{l} = m-n+1-\frac{n+1}{2n+1}(m-n) \ge l.$$

Now $\nu(n,l) \le \nu(n,\tilde{l})$, where

$$\nu(n,\tilde{l}) = \frac{n(2mn+2m-4n^2+3n+3)}{4n+2}.$$

Now note $\nu(n,\tilde{l}) \ge \mu(n,\tilde{h})$ if $n=1$, and $\mu(n,\tilde{h}) \ge \nu(n,\tilde{l})$ if $n=2,3$.

We now prove the theorem for the case $n > 3$. Here we let

$$\tilde{h} = \frac{m-n+1}{2} \geq h$$

and

$$\tilde{l} = m - n + 1 - \frac{m-n}{2} \geq l.$$

1 In case $m \leq 3n-7$ we have $\tilde{h} \leq n-3$ and $\tilde{l} < n$; hence the second branch of μ and the first branch of ν have to be used. Thus,

$$\mu(n,h) \leq \mu(n,\tilde{h}) = \frac{m-n+11}{8}(m-n+1),$$

$$\nu(n,l) \leq \nu(n,\tilde{l}) = \frac{m-n}{8}(m-n+10)+1,$$

and $\mu(n,\tilde{h}) \geq \nu(n,\tilde{l})$.

2 In case $m = 3n-6$ we have $h = n-3$, $l = n-2$, and the theorem can be verified explicitly.

3 In case $3n-5 \leq m \leq 3n-2$ we have to use the third branch of μ and the first branch of ν. We obtain

$$\mu(n,h) \leq \mu(n,\tilde{h}) = \frac{n}{2}(m-2n+6)-3$$

and

$$\nu(n,l) \leq \nu(n,\tilde{l}) = \frac{m-n}{8}(m-n+10)+1.$$

For each $3n-5 \leq m \leq 3n-2$, $\mu(n,\tilde{h}) \geq \nu(n,\tilde{l})$.

4 In case $m = 3n-1$ we have $h = l = n$, and $\mu(n,h) > \nu(n,l)$ can be bounded as in the previous case.

5 In case $m > 3n-1$ we have $h \geq (m-n)/2 > n-1/2$ and $l \geq m-n+1-(m-n+1)/2 > n$. Using the third branch of μ and the second branch of ν we have

$$\mu(n,h) \leq \mu(n,\tilde{h}) = \frac{n}{2}(m-2n+6)-3$$

and

$$\nu(n,l) \leq \nu(n,\tilde{l}) = \frac{n}{2}(m-2n+2)+\frac{m}{2}.$$

Now, if $m \leq 4n-6$ then $\mu(n,\tilde{h}) \geq \nu(n,\tilde{l})$; if $m > 4n-6$ then $\nu(n,\tilde{l}) > \mu(n,\tilde{h})$.

□

Our method for exact division on two processors will be most useful on a shared-memory machine when invoked by an algebraic algorithm with a higher level of parallelism. When several exact divisions have to be executed in parallel, our method will add another level of parallelism to the program.

6. Experiments

We ran a sequential and a parallel implementation of our method on the shared-memory architecture of the *Sequent Symmetry*. We used the `PACLIB` environment (Hong

et al. 1992) which combines the computer algebra library `SACLIB` (Collins *et al.* 1993) with the parallel features of the μSystem library (Buhr *et al.* 1991).

Table 1 lists computing times and computing time ratios for inputs of various lengths. The row heading 20/15 refers to a dividend of 20 words and a divisor of 15 words. The column heading IQR stands for the `SACLIB` implementation of Knuth's integer quotient-remainder algorithm, Algorithm D; IEQ stands for the `SACLIB` implementation of Jebelean's integer exact quotient method; Sequential and Parallel refer to a sequential and a parallel implementation of our new method. The sequential implementation splits the quotient as in the proof of Theorem 4.1; the parallel implementation splits the quotient as in the proof of Theorem 5.1.

Table 2 has the same structure as Table 1, but instead of the computing time it lists the number of digit products that were computed. Those numbers agree very well with the bounds given in Theorems 4.1 and 5.1. The ratios of those numbers with respect to the number of digit products required in the classical algorithm are a measure for the expected speed-up.

The observed speed-up agrees well with the expected speed-up when the quotient is more than 30 words long. When the quotient is shorter, certain linear-time operations are significant. In particular, since `PACLIB` integers are represented as linked lists, we copy the inputs from lists to arrays and the output from an array to a list.

Surprisingly, the observed speed-up of IEQ and Sequential in the third section of Table 1 exceeds the expectations. This can be explained by noting that IQR and Algorithm H use digit divisions in order to determine the quotient digits. Table 2 counts those digit divisions as digit products, but the true cost of digit division is about 2.5 times the cost of a digit product in the `SACLIB` implementation we used. Hence the unexpected speed-up is due to the replacement of a linear number of divisions by multiplications.

Finally we note that the parallel algorithm provides a significant speed-up even when the quotient is only 10 words long. In our experiments the efficiency of the parallel implementation exceeds 83% for quotients longer than 25 words and reaches 93% in some cases.

Since our method is in the same complexity class as classical division, one might ask for which length of the operands one should use an asymptotically fast method instead.

Asymptotically fast algorithms for division are based on an iterative computation of the inverse that uses Newton's method. Knuth (1981, Section 4.3.3.D) describes such a method and analyzes the time required to divide one n-bit number by another. We adapt his analysis to estimate the number of digit products needed for dividing a $2n$-word number by an n-word number.

Each Newton step requires two multiplications that are performed by an asymptotically fast algorithm. The only such algorithm which is useful for integers shorter than 400 words is the multiplication algorithm due to Karatsuba and Ofman (1962). An estimate (along the lines suggested by Knuth) of the number $R(n)$ of digit products required by Newton-inversion leads to $R(n) = 2T(4n) + 2T(2n) + 2T(n) + 2T(n/2) + ...$, where $T(n)$ digit products are needed for the multiplication of n-digit numbers. Using the property $T(2n) = 3T(n)$ of the Karatsuba algorithm, one gets $R(n) \approx 27T(n)$ digit products; thus the entire division requires roughly 30 $T(n)$ digit products.

In order to obtain an estimate for the break-even point of our method with Newton-division, we estimate $T(n) = n^{\log_2 3} \approx n^{3/2}$. If n is the break-even point, it will satisfy $30n^{3/2} \approx n^2/4$, and thus $n \approx 15,000$.

200/50	7550	6475	*1.2*	5245	*1.4*	2650	*2.8*

Since this value is very large one might obtain a smaller break-even point when Karatsuba's algorithm is replaced by FFT-based multiplication (Schönhage and Strassen 1971). The number of digit products required by this algorithm has not been analyzed in the literature. Since such an analysis is outside the scope of this paper, we just note that Schönhage himself (1994, Section 6.1.53.) uses the classical method whenever the dividend is shorter than 240 words. We believe that the break-even point with our method is much higher than this.

7. Acknowledgements

We thank George Collins for pointing out a flaw in the earlier version of Algorithm H. We also thank one of the anonymous referees for noting non-obvious typographical errors.
